

Field Model: An Object-Oriented Data Model for Fields

Technical Report NAS-01-005

pmoran@nas.nasa.gov

Abstract

We present an extensible, object-oriented data model designed for field data entitled *Field Model (FM)*. *FM* objects can represent a wide variety of fields, including fields of arbitrary dimension and node type. *FM* can also handle time-series data. *FM* achieves generality through carefully selected topological primitives and through an implementation that leverages the potential of templated C++. *FM* supports fields where the nodes values are paired with any cell type. Thus *FM* can represent data where the field nodes are paired with the vertices (“vertex-centered” data), fields where the nodes are paired with the D -dimensional cells in \mathbf{R}^D (often called “cell-centered” data), as well as fields where nodes are paired with edges or other cell types. *FM* is designed to effectively handle very large data sets; in particular *FM* employs a demand-driven evaluation strategy that works especially well with large field data. Finally, the interfaces developed for *FM* have the potential to effectively abstract field data based on adaptive meshes. We present initial results with a triangular adaptive grid in \mathbf{R}^2 and discuss how the same design abstractions would work equally well with other adaptive-grid variations, including meshes in \mathbf{R}^3 .

CR Categories: E. Data (large); I.1.3 Languages and Systems, Evaluation strategies; I.3.8 Computer Graphics Applications

Keywords: data models, object-oriented, C++, templates, scientific visualization, demand-driven evaluation.

1 Introduction

Underlying virtually every object-oriented visualization system is a data model. The data model forms a key part of the system design, effectively spelling out the types of data that can be analyzed by the system. A well-designed data model component can significantly enhance the capabilities of the overall system. For example, the developers of OpenDX (formerly IBM Data Explorer) often cite the consistent, unified nature of the DX data model as one of the key reasons for the success of their system [13, 1]. For large data visualization, the data model can have a significant impact on system efficacy. Poorly chosen abstractions can lead to performance problems or make development awkward. Well-designed abstractions can enhance code reuse and enable the coupling of components in new and interesting ways.

A recent trend in numerical computing is the growing popularity of adaptive meshes. Adaptive meshes increase or decrease resolution automatically as required by a simulation code. Adaptive meshes free the scientist from having to construct a mesh initially that completely anticipates where high resolution will be required. Adaptive meshes are also a natural choice when the resolution required in various regions of the domain changes over the course of the simulation, for instance, following a shock wave. Adaptive

mesh techniques are often implemented as parallel algorithms, requiring careful load balancing and communication strategies in order to be most effective. Unfortunately, adaptive meshes tend not to match well with the data models underlying current general visualization systems, prompting mesh library developers to resort to developing visualization modules custom to their mesh design.

For those in the visualization community, adaptive meshes offer the possibility of new and interesting research topics. For example, one might want to couple various multi-resolution visualization techniques with the adaptive mesh data structures. For visualization system developers, adaptive meshes are a challenge. There are a number of current adaptive mesh development efforts, each with its own custom algorithms and data structures. One would like to apply the wealth of visualization techniques that have already been developed, yet one is likely not to have the resources to devote to interfacing to each adaptive mesh variation. This is where a carefully designed data model comes in. With appropriately chosen abstractions, a data model can insulate the visualization techniques from the majority of the idiosyncrasies of the mesh and field data structures. A carefully designed model can also enhance modularity: newly added mesh and field types in the future should not require significant modifications to existing code.

In general, the advantages of a good data model are not limited to adaptive meshes alone. Overall, our goal is to provide a common model for field data that will enhance the sharing of data sets and of visualization technique implementations. In the next section we provide an overview of some of the key concepts in the *FM* design that are intended to take us towards our goal. Following that we survey related data model work within the visualization community. Next, we discuss key features of the *FM* design, and then present current results. Finally, we conclude with a discussion of future plans for the *FM* project.

2 Field Model Concepts

Field Model objects are embedded in \mathbf{R}^D , also known as *physical space*. Objects in \mathbf{R}^D are also said to have a *physical dimensionality* of D . The regions in \mathbf{R}^D where fields are defined are discretized by meshes, which in turn are composed of cells. A k -cell is a subset of \mathbf{R}^D that is homeomorphic (topologically equivalent) to a k -ball. Cells in *FM* are currently all linear objects. A 0-cell is a vertex, a 1-cell is an edge, 2-cells include triangles, quadrilaterals, and other polygons. Hexahedra, tetrahedra, pyramids and prisms are all examples of 3-cells. Every cell σ has a set of vertices. We use a more general concept of face than some are familiar with: a *face* of σ is specified by a non-empty subset of the vertices of σ ¹. For example, a hexahedron has not only quadrilateral faces, but also vertex and edge faces. Every cell is also a face of itself. The general face definition enables us to develop a more uniform treatment of objects

¹If a cell σ is not a simplex, then not every subset of the vertices of σ constitutes a face. In practice it is clear which subsets define valid faces.

* Mail Stop T27A-2, Moffett Field, CA 94035

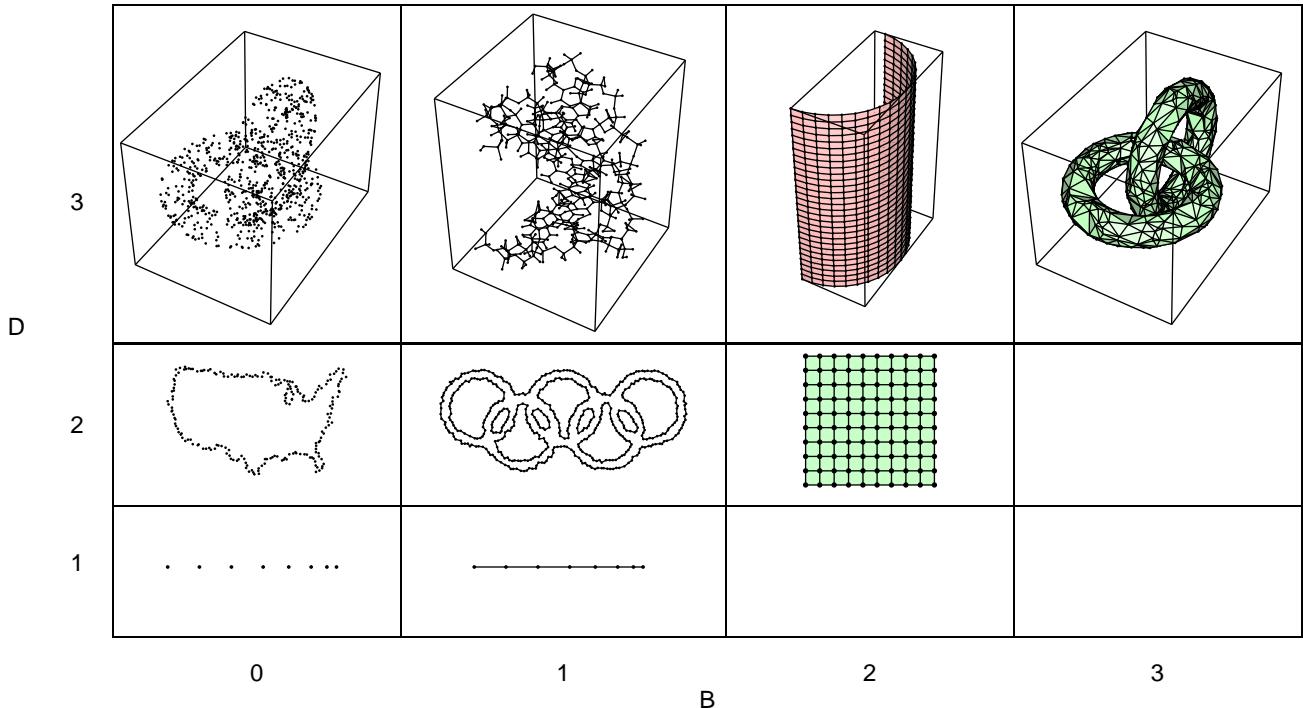

Figure 1: Example *FM* meshes organized in columns and rows by base dimensionality (B) and physical dimensionality (D), respectively. Note that the model is general enough to represent not only the input to visualization techniques, but also the output. For example, regular meshes in \mathbf{R}^2 ($(B,D) = (2,2)$) could serve as the underlying discretization for images, and surfaces in \mathbf{R}^3 naturally correspond to $(2,3)$ meshes.

with general dimension. A *mesh* \mathcal{M} is a finite set of cells such that if $\sigma \in \mathcal{M}$, and τ is a face of σ , then $\tau \in \mathcal{M}$. Typically, cells in a mesh share common faces, so for example two tetrahedra can share triangle, edge, and vertex faces. If the cells with the highest dimensionality in mesh \mathcal{M} are B -cells, then \mathcal{M} is a B -mesh, and \mathcal{M} has a *base dimensionality* of B . The base dimensionality of a mesh must be less than or equal to its physical dimensionality. The *shape* of a mesh \mathcal{M} is the space occupied by the union of all the cells of \mathcal{M} . In most cases, the shape of a B -mesh is equivalent to a B -manifold with boundary. In order to rule out some cell collections that do not have a manifold shape, we require that every cell in a B -mesh \mathcal{M} must be the face of some B -cell in \mathcal{M} . This requirement, for instance, rules out cases where we have a surface ($B = 2$) with spurious edges and vertices that are not part of the surface.

Figure 1 illustrates example meshes that can be constructed in *FM*. Note that *FM* meshes can represent familiar objects such as regular meshes, curvilinear meshes, and tetrahedral unstructured meshes. Note too that our definition is general enough that we can represent objects less commonly thought of as meshes, such as a collection of vertices and edges signifying the atoms and bonds of a molecule ($B = 1, D = 3$). Also, note that the molecular example is a case where the set of cells adheres to our mesh definition, but the shape of the mesh is non-manifold.

A *field* defines a function within a region of space. In *FM*, each field object has a set of values called *nodes* (which can be accessed on demand), a mesh, and a pairing between the k -cells in the mesh and the nodes. The value of k for a particular field is known as its *node association index*. The base and physical dimensionalities of a field are the dimensionalities of its underlying mesh. For fields with base dimensionality B , the most common node association indices seen in visualization data are 0 (“vertex centered”) and B (typically called “cell centered”). Other node association indices tend to be underrepresented in visualization studies, though they are still

important scientifically. Node association index 1 fields often occur in electromagnetics simulations as well as some adaptive mesh systems, where adaptation criteria are paired with the edges. Node association index 2 fields are useful in some flow studies, where fluxes are tracked at the 2-cells in order to verify the correctness of the simulation.

For a field with node association index k , the user can request a single value at a particular k -cell or request multiple values at a j -cell, $j \neq k$. We define later how the field selects node values in the case where $j \neq k$. The user can also request a field value at an arbitrary point in physical space, or for fields based on meshes with structured behavior, at an arbitrary point in base space. In response to such queries, fields return an integer code indicating whether the query was successful (e.g., depending upon whether the given point was within the part of the domain where the field is defined), and a field value. Appropriate interpolation techniques are fairly well agreed upon for fields with node association index 0; for other node association indices appropriate interpolation methods are still under investigation.

Before proceeding with a description of the *FM* design and implementation, we review previous data model work.

3 Related Work

The importance of a well-designed data model has been recognized early on in the visualization community, and there have been a number of efforts to develop a general design with a strong, formal foundation. One of the earliest was the fiber bundle model by Butler and Pendley [5]. Their model was inspired by the mathematical abstraction of the same name. Fiber bundles have proven to be somewhat difficult to implement in their pure form, though the concepts have inspired several follow-on efforts. The original fiber bundle abstractions did not provide a convenient means to access

the underlying discretization (mesh) of a data set. This was a problem since many visualization algorithms operate by iterating over various types of cells of the mesh.

One system in particular that has been influenced by fiber bundle concepts is OpenDX (formerly IBM Data Explorer[13, 1]). Beginning with Haber et al [8], the fiber bundle model was adapted into a model that would support a general-purpose data-flow visualization system. OpenDX can handle fields with node association indices 0 or B , where B is the base dimensionality of the field. OpenDX does not support adaptive meshes, though more recent work by Treinish [23] describes a model that would accommodate such data.

Another field modeling effort was the Field Encapsulation Library (FEL) project, first presented at Visualization '96 [3]. FEL excelled with the multi-block curvilinear grids that are popular in computational fluid dynamics applications. FEL differed from most other modeling efforts in that it defined separate class hierarchies for meshes and fields, rather than a single combined object type. A second version of FEL, FEL2, followed after a basic redesign and total rewrite [16, 15]. FEL2 introduced fundamental design features that enabled the library to operate with far larger data sets, including a consistent demand-driven evaluation model [14] and the integration of demand-paging techniques [6]. FEL2, like the original version of FEL, assumed that all objects were in \mathbf{R}^3 physical space, and that all fields effectively had a node association index of 0.

The Visualization Toolkit (vtk) [20], like OpenDX, is an open source visualization system with a fairly general data model. The vtk data model uses an extended concept of cells, including such primitives as polylines and triangle strips as cell types. Recent extensions [12] have focused on enabling the data model (and thus the whole system) to handle large data. Like *FM*, vtk utilizes a demand-driven evaluation strategy. In vtk, visualization techniques negotiate with a data source in order to determine appropriate streaming parameters, then the streaming commences. *FM* demand-driven evaluation is maximally fine-grained: visualization techniques request data one cell at a time, and the lazy evaluation happens at the same granularity. The *FM* approach leads to more function calls between the data consumer and producer, while the vtk approach implies that the data consumer has to know more about the characteristics of the data set it is accessing.

Another object-oriented data flow visualization system intended for large data visualization is SCIRun [2, 19]. One distinguishing characteristic of the SCIRun development effort was the focus on computational steering, i.e., analyzing data from a simulation and modifying simulation parameters, as the simulation is running. SCIRun also allowed for some mesh adaptation during a simulation run. The data model was not the primary focus of the overall development effort.

VisAD [10, 9] is a relatively general, object-oriented model for numerical data. The user can construct data objects with a style similar to expressing mathematical functions. In contrast to the models described previously, VisAD is implemented in Java. The VisAD model is quite flexible, though the Java implementation makes it less suitable for very large data. The VisAD model does put more effort into the inclusion of metadata – data about data – than most other designs. For example, VisAD provides for the specification of the units of measurement. Thus, for example, VisAD users should be less likely to confuse distances measured in miles with distances measured in kilometers.

4 Design and Implementation

Object-oriented design is hard. As Gamma et al. point out:

Experienced object-oriented designers will tell you that a reusable and flexible design is difficult if not impossi-

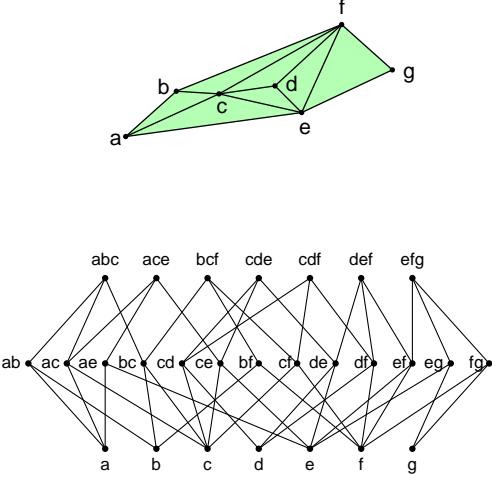

Figure 2: A small 2-mesh and its corresponding incidence graph. Answering faces queries is equivalent to following paths upwards or downwards in the graph.

ble to get “right” the first time. Before a design is finished, they usually try to reuse it several times, modifying it each time [7].

In the case of the design of *FM*, we benefit from our experience with the original [3] and second generation [16, 15] Field Encapsulation Library (FEL) projects. Both generations had relatively demanding performance requirements from applications such as Virtual Windtunnel [4]. Both also faced large data challenges. The second generation FEL was used by several different applications, providing reuse cases that helped us refine the class interfaces.

In *FM*, as in FEL, the two main types of objects in the model are meshes and fields. We discuss key features of both types next.

4.1 Shared Mesh and Field Interface

Both mesh and field classes inherit interface from the class `FM_field_interface<B,D,T>`, where the template arguments B , D and T specify the base dimensionality, physical dimensionality and node type, respectively. For meshes, the node type is the coordinate type: `FM_vector<D,FM_coord>`. The interface class specifies the member functions `at_cell`, `at_base`, and `at_phys`. The `at_cell` call takes a cell argument and appends values to a C++ standard library vector [11] passed in by pointer. The `at_base` and `at_phys` member functions provide access to field values at a single point in base space or physical space, respectively. We provide detail on the access function semantics below.

4.2 Mesh Interface

In general an application can access two types of information from a mesh object: geometric and topological. Geometric information is accessed primarily through the `at_cell` call, which produces the coordinates of the vertices of its cell argument. The `at_base` call takes a point in base coordinates and produces physical coordinates, thus it provides a means to convert between the two coordinate systems. (There is also a routine to do the opposite conversion). The `at_phys` call may at first seem redundant for meshes, but via its integer return value it does provide a means for verifying whether a given physical point is within the region where the field is defined.

FM mesh objects have several member functions that provide topological information. Here we focus on one particular method, `faces`, that is key to the general node association design. To illustrate the `faces` method, we consider the small 2-mesh in Figure 2. Below the the mesh is an incidence graph which captures all the face relationships of the mesh. Each row of nodes² in the graph corresponds to a particular cell dimensionality, with the rows ordered by increasing dimensionality from bottom to top. The graph contains an edge between nodes representing a k -cell σ and a $(k+1)$ -cell τ if σ is a face of τ . The `faces` methods takes a k -cell σ and an integer argument j . If $j < k$, then `faces` returns the j -cells that are faces of σ . If $j > k$, then `faces` returns the j -cells that σ is the face of. If $j = k$, then `faces` returns σ . In terms of the graph in Figure 2, the $j < k$ case is equivalent to following all paths downward to the j th row from the node corresponding to σ ; the $j > k$ case is equivalent to following all paths upward instead of downward. For those familiar with algebraic topology, the functionality of the `faces` call is essentially equivalent to the closure and star operators combined [17]. The `faces` method has many uses, for example it may be used for obtaining the edges of a given hexahedron. We will see how `faces` is used in conjunction with general node association below in Section 4.4.

The *FM* mesh interface also supports iterator functionality compatible with the C++ standard library [11]. Meshes behave as collections of cells, and one can iterate over the cells. Unlike standard library collections, mesh objects provide a richer set of iteration possibilities. Typically one wants to iterate over cells of a particular dimension, or some other subset of the total collection of cells. *FM* provides this control via optional arguments to the `begin` iterator initializer call. Other than that difference, *FM* iterator style is compatible with the standard library, and one should be able use any of the standard library algorithms that operate with a collection that provides a `const_iterator`.

4.3 Mesh Implementation

Figure 3 summarizes the *FM* mesh hierarchy. All mesh objects share common interface defined by `FM_mesh_` and `FM_mesh<B,D>`. The subclasses also share implementation through inheritance. For example, topological methods such as `faces` are implemented in `FM_structured_mesh<B,D>` and used by all structured mesh subclasses. Meshes are also responsible for point location and contribute geometric information that is used for interpolation. Efficient point location is critical in a high-performance field model, as it is an intermediate step when computing field values at arbitrary points in space. Through the class hierarchy we are able to provide point location routines that exploit characteristics of various types of meshes in order to provide increased performance.

4.4 Field Interface

Fields are all templated on base dimensionality, physical dimensionality and node type. *FM* uses the same source for scalar, vector and in general tensor fields — all are instantiated from the same class definitions. The fundamental field member function for obtaining field values is `at_cell`, which produces one or more field values, returning them in a C++ standard library vector object [11]. For a field with node association index k , an `at_cell` call with a k -cell argument will produce a single field value. The same call with a j -cell argument, $j \neq k$, first would use the `faces` call on the underlying mesh to convert the j -cell into a collection of k -cells. Then, for each of the resulting k -cells the field would append a single value to the result collection. Thus, for example, a node association index 0 field given a hexahedron argument would produce

```
FM_mesh_
  FM_mesh<B,D>
    FM_structured_mesh<B,D>
      FM_curvilinear_mesh<B,D>
      FM_regular_interval
      FM_irregular_interval
      FM_product_mesh<B,D>
        FM_regular_mesh<B,D>
      FM_unstructured_mesh<B,D>
      FM_multimesh<B,D>
    FM_time_series_mesh<B,D>
```

Figure 3: A synopsis of the main mesh classes, with the inheritance hierarchy signified by indentation. The integer template arguments B and D to `FM_mesh<B,D>` and the classes below it specify the base and physical dimensionality, respectively. The `FM_mesh_` parent class provides a convenient handle when an application only requires the portion of the mesh interface that is not dependent upon the mesh dimensionality, e.g., the iterator interface.

```
FM_field_
  FM_field<B,D,T>
    FM_core_field<B,D,T>
    FM_multi_field<B,D,T>
    FM_unary_derived_field<B,D,T>
    FM_binary_derived_field<B,D,T>
    FM_time_series_field<B,D,T>
```

Figure 4: A synopsis of the main field classes, with the inheritance hierarchy signified by indentation. The B and D template arguments have the same meaning as for meshes. The T template argument specifies the field node type, e.g., `float`. The purpose of the `FM_field_` parent class is analogous to that of `FM_mesh_`: it provides a convenient handle when an application only requires the portion of the field interface that is not dependent upon the template arguments.

8 values, 1 for each vertex. Or, for example, a node association index 3 (“finite volume”) field `at_cell` call with a vertex argument would return in general 8 values. We say “in general” since a vertex at the boundary of the mesh is the face of fewer than 8 hexahedra.

The utility of the `at_cell` definition becomes further apparent when we consider cases where we have a field with one particular node association index, but want it to behave like another. Our approach would be to define an adapter class [7], derived from `FM_field<B,D,T>`, with its own `at_cell` method implementation. For instance, consider the case where we have a visualization algorithm that expects a single value when calling `at_cell` with a vertex, but our field has a node association index not equal to 0. The adapter would take an incoming vertex argument and call `at_cell` on the adapted field. The multiple values received in response could be averaged (perhaps with some weighting factors) to produce the final single value response. Such an adapter would enable us to reuse some older visualization techniques that make vertex-centered data assumptions.

4.5 Field Implementation

The `FM_field_` class hierarchy is summarized in Figure 4. The subclasses are primarily responsible for providing implementations for the `at_cell` member function. Core fields produce values from a memory buffer. `FM_multi_field<B,D,T>` represents fields consisting of multiple subfields; `at_cell` calls are delegated to the appropriate subfield. The derived field classes produce values on demand, applying a mapping function to the values produced by

²Note that *graph nodes* and *field nodes* are different concepts.

Mesh	Card ₀	Card ₁	Card ₂

Level 4	380877	1505024	1003313
Level 5	488574	1935619	1291834

Table 1: Cell set cardinalities for the 0-cells, 1-cells, and 2-cells in the airfoil example illustrated in Figure 5. The levels denote the number of refinement steps taken.

`at_cell` calls on the underlying fields.

The `FM_field<B,D,T>` class provides default implementations for the `at_phys` and `at_base` methods. Both implementations operate by locating a cell containing the given point, obtaining field values in the neighborhood of the point using `at_cell`, and then interpolating based on the geometry of the cell. Since both `at_phys` and `at_base` are implemented in terms of `at_cell`, field subclasses are not required to provide implementations of these two functions. Nevertheless, some subclasses do provide their own implementations in order to employ optimizations that are specific to certain field types.

4.6 Time

In the previous sections we have said little about time, but this is not because time-varying data is unimportant. To the contrary, many large data sets come in the form of a time series. There are two main strategies we could choose in order to address the needs of time-varying data in *FM*. One approach would be to simply treat time as an added dimension, utilizing the general-dimension mechanisms in we have already developed. The alternative would be to treat time as special, distinct from the spatial coordinates. At first glance, the former strategy may seem more appealing – we would like to reuse implementation when we can – but we decided to go the latter route instead, for several reasons. First, the spatial and temporal resolutions of the data can be dramatically different. Especially in post-processing applications, what is saved of the simulation is typically down sampled in time from the resolution used during the run. This implies we may want to do spatial and temporal interpolation differently. Second, many visualization techniques are designed to work at some instance in time, and they do not handle time explicitly. If time were an added dimension, then the user of *FM* would need to reduce the data dimensionality before passing the data to the visualization technique. While such a design is possible, we concluded that it could be somewhat awkward for our users, and there is some question as to how great of a performance hit we would take if we were to employ such an approach.

In *FM*, time-varying meshes and fields are represented by the classes `FM_time_series_mesh<B,D>` and `FM_time_series_field<B,D,T>`, respectively. Base position, physical position, and cell arguments all contain a time member. Objects that do not vary with time ignore this member. Time series objects use the time member to index into the series and as part of the interpolation process when needed. Within this design, visualization techniques are free to request values in space and time as needed by the particular algorithms.

5 Results

5.1 2-D TAG

As a demonstration of the *Field Model* capabilities, we consider a 2-D Triangular Adaptive Grid (TAG) code that has served as the

basis for previous research efforts on adaptive grid techniques [18]. The TAG system is designed to be relatively insulated from a particular flow solver. TAG provides mesh geometry and connectivity information used by the solver; the solver in turn computes field node values and adaptation criteria that are associated with the mesh edges. Based on the adaptation criteria, the TAG system refines or coarsens the mesh. Figure 5 illustrates the airfoil test case that we consider here. Table 1 quantifies the mesh size in terms of the number of k -cells, $k = 0..2$, for each level of refinement.

Our motivation for choosing the TAG 2-D example is to test extensibility, in particular, with an adaptive mesh object. It is neither feasible nor desirable for *FM* to provide built-in support for every mesh data structure; the library implementation would become too bulky and difficult to maintain. Instead, our goal is a design that is modular enough that new types of meshes can be added without significant modification to existing parts of the model. To be successful in this endeavor, we have three criteria. First, the class interfaces should be general enough to be applicable to a variety of object types. So far we consider ourselves to have met this requirement. *FM* can represent a variety of objects, including structured and unstructured objects and multi-block objects. We have not encountered significant limitations due to the interfaces. Second, the interface abstractions should not cause us to suffer an unacceptable loss in performance. We address this issue below. Finally, the class design should support reuse of parts of the implementation, so that newly introduced mesh and field types do not have to reimplement common routines. Our design has been successful in this respect as well. For 2-D TAG, we defined a new class `TAG2D.unstructured_mesh`, which is derived from `FM_unstructured_mesh<2,2>`. Note that the TAG2D class is not templated; the base dimensionality and physical dimensionality are hard-coded in the 2-D TAG implementation that we obtained. Our TAG2D class must provide implementation of some basic member functions such as `at_cell` and `faces`, since these functions refer to TAG-specific data structures. Other functionality, such as iterator support, is inherited from `FM_unstructured_mesh<2,2>`; our TAG class can reuse the existing code.

The version of the 2-D TAG code we adapted for our example here executes serially. Oliker and Biswas [18] also have versions of the same code designed for parallel architectures, including message passing systems. We do not have experience yet with how well *FM* would accommodate such generalizations, but we are interested in investigating this. There is also a 3-D version of the adaptive grid code, developed by the same research group, that is analogous in many respects to 2-D TAG. The 3-D version contains non-simplicial cells, including pyramids, prisms and hexahedra, which should provide some additional challenge, although we do not anticipate any fundamental problems adapting such objects.

5.2 Performance

Field Model at its heart is about abstractions, and it is natural to ask what cost one has to pay for the benefits of abstraction. This in general is a difficult question to answer, because:

- cost is relative to some alternative, and what alternatives we have vary from case to case;
- how much abstraction overhead is apparent depends on the balance between data access and computation using the data;
- with large data, access time can be significantly influenced by the locality or lack thereof in data access patterns.

Despite these difficulties, it is still important to quantify the performance of the data model. We present the results from two initial

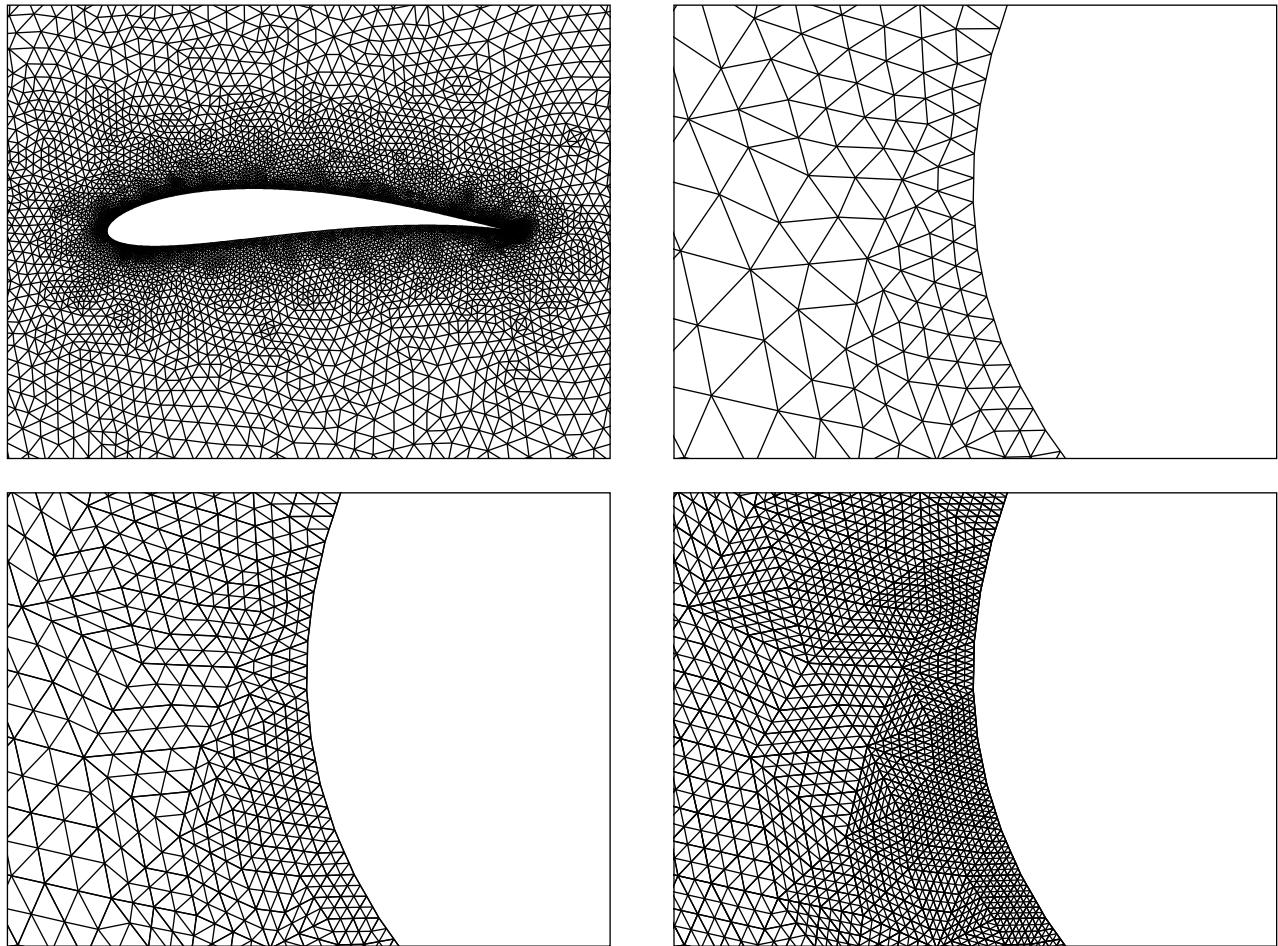

Figure 5: The airfoil data set with 2-D TAG. At the upper left is a close-up of the whole airfoil. At the upper right is a much closer view of the leading edge of the airfoil. The two images in the lower row display successive refinement iterations within the same region.

Mesh	Bounding Box		Edge Drawing	
	Abstract	Direct	Abstract	Direct
Initial	13.9	1.1	1395.9	1324.5
Level 1	23.5	1.8	2634.7	2555.9
Level 2	56.3	4.3	6929.4	6583.7
Level 3	152.4	11.7	20276.7	18841.9
Level 4	343.8	26.4	45754.7	44351.6
Level 5	462.8	35.7	59516.6	58007.2

Table 2: Initial *FM* example timings, in msec. The “Bounding Box” columns illustrate a worst case scenario for *FM*: we compare an algorithm written using *FM* to a hand-coded implementation that accesses the data structures directly, and the amount of compute relative to each data access is small. In this scenario the *FM* version comes out over an order of magnitude slower. The “Edge Drawing” columns illustrate a scenario that may be more typical. Once again we compare an algorithm written using *FM* to a hand-coded implementation that accesses the data structures directly, but in our second scenario the compute time is more significant. In this second scenario, the *FM* version is slower, but by roughly only 5%.

tests based on the 2-D TAG example discussed in the previous section. Our first test involves computing the bounding box of the TAG mesh. This test is in many respects a worst case scenario because we compare the abstract *FM* method to a hand-coded C-style implementation that has direct access to the data buffers, the amount of computation using the data is minimal, and the data are not really large enough for cache-miss rates to dominate. The columns under “Bounding Box” in Table 2 summarize the results for the example airfoil data set, measured on a 195 MHz, dual processor SGI Onyx2 workstation with 512M of memory. The worst case does look pretty bad: the difference in total times in each case is over an order of magnitude. Still, depending on the application, the abstract performance may be fast enough.

As a second example, we consider a scenario where we generate postscript images consisting of the edges in the TAG mesh. We time the actual code we used to generate the images in Figure 5. Like the first scenario, we compare access through *FM* to hand-coded direct access to the data structures. Unlike the first scenario, the computation involves some simple transformations followed by a write to our postscript file. This is clearly more expensive than our bounding box computation. The columns under “Edge Drawing” summarize the results. The *FM* version runs slower, but by roughly only 5%. For this application the overhead is likely to be acceptable.

The timings in Table 2 clearly are not a thorough assessment of *FM* performance. *Field Model* is still relatively early in its development process, and we have done little performance tuning so far. Our plan is to port the VisTech library [21] to *FM* in the near future. VisTech consists of a collection of standard visualization algorithms, written in terms of FEL2 [16, 15]. We will be able to compare *FM*/VisTech performance with that of FEL2/VisTech, and in some cases with implementations hand-coded for specific mesh and field types. VisTech applications will provide examples with more typical balance between data access and computation as well as relatively typical data access patterns for visualization applications.

6 Conclusion

We have presented an overview of *Field Model* (*FM*), an object-oriented data model for mesh and field data. *FM* benefits significantly from our experiences with FEL2 [16, 15], an earlier effort focused on the development of high-performance library for large data. *FM* goes beyond FEL2 in generality: *FM* can represent data

with general base and physical dimensionality as well as fields with general node association. Furthermore, we anticipate that *FM* will be able to successfully handle adaptive mesh types. Our experience so far with the 2-D TAG [18] adaptive code confirms our expectations.

Two of the primary design goals of the *FM* project are modularity and extensibility. Our vision is that *FM* will serve as a common model where others in the community can contribute extensions specific to their mesh and field objects. The incentive would be that data brought into the shared model could be analyzed by what we hope will be a wide collection of analysis techniques written in terms of the model. Towards this end, we are working to establish *FM* as an Open Source [22] project, with its development home on SourceForge. We have established a site there (<http://field-model.sourceforge.net>), and we currently have a few initial files uploaded to the repository. We anticipate that by Vis’01 all the source used to create objects such as those displayed in this article will be available from our site.

Acknowledgements

We would like to thank Ernst Mücke for the interlinked tori point set used in Figure 1. We would also like to thank Rupak Biswas for providing the 2-D TAG code and example data used in Section 5.1. We are also grateful to Pete Vanderbilt and all the members of the Data Analysis Group for helpful insights. Finally, we would like to thank VA Linux for their ongoing support of the Open Source [22] software movement, and SourceForge in particular.

/*
 * NAME: FM_ostringstream.h
 *
 * WRITTEN BY:
 *   Patrick Moran      pmoran@nas.nasa.gov
 *
 * DESCRIPTION:
 *   FM_ostringstream provides a work-around for systems
 *   that do not have std::ostringstream yet, using the
 *   deprecated std::ostream. We basically define a
 *   new class (FM_ostringstream) derived from std::ostream,
 *   with a redefined str() method that handles string termination
 *   and memory management properly.
 *
 * SEE ALSO:
 *   N. Josuttis. The C++ Standard Library: A Tutorial and
 *   Reference, Addison-Wesley, 2000, pages 649-651. This
 *   is the best reference I have found that explains how
 *   stringstream works.
